Question dropped: Is Ashford's injury rate different from the rest of the league once player profiles are taken into account?

Why we did not pursue a team-level comparison of injury rates. We considered testing whether Ashford's injury rate differs from other clubs' once player characteristics are accounted for. We decided against it for two reasons. First, presenting it separately would have meant our three analyses covered only two distinct areas. Second, our exploratory check suggested a null result: once age, training load and previous injuries were in the model, team added no explanatory power (likelihood-ratio test, $p \approx 0.59$). That is worth knowing, but there is little to interpret beyond "no evidence of a club effect". Second, each team has only about 24–28 players, which leaves little power to detect differences between individual clubs, so even a real effect would be estimated imprecisely. We judged that a question drawing on both datasets would give the club a broader picture and let us show a wider range of modelling.
